Inoculating legumes with rhizobia can achieve substantial increases in legume nodulation, grain and biomass yield, nitrogen fixation and post-crop soil nitrate levels.

**KEY POINTS**

- The benefits of inoculating legumes with rhizobia (soil bacteria that fix nitrogen) have been recognised in Australian agriculture for more than 100 years.
- Inoculation can result in increases in legume nodulation, grain and biomass yield, nitrogen fixation and post-crop soil nitrate levels.
- These gains are highest when the legume is grown in nil-rhizobia or low-rhizobia soil.
- Benefits can be marginal in soils already containing high numbers of compatible rhizobia.
- Legumes have specific requirements for rhizobia: there are 39 different inoculant groups produced commercially in Australia.
- Formulations for inoculants include peat, clay and peat granules, freeze-dried cultures and liquid cultures.
- Inoculant quality is underpinned by commercial in-house testing and the National Code of Practice and Quality Trademark (Green Tick Logo).

Compatible rhizobia

N fixation by the legume-rhizobia symbiosis does not happen in all soils. Compatible, effective rhizobia must be present before nodulation and N fixation can occur.

When a legume is grown for the first time in a particular soil, it is unlikely that the correct rhizobia will be present. Therefore the rhizobia must be supplied in highly concentrated form as inoculants.

**Early days**

Australian farmers have embraced legumes and legume inoculation from the outset. Australian agricultural soils are naturally low in plant-available N but the use of fertiliser N has not always been an affordable option.

Cultivated legumes, mainly pasture and forage species, have had to be able to effectively fix N in the soil.

In 1896, the famous agricultural chemist F.B. (Frederick) Guthrie wrote about legume N fixation in the *Agricultural Gazette of New South Wales* saying that “it will prove to be one of the most valuable contributions ever made by science to practical agriculture.”

More than 100 years later, Australian farmers sow inoculated legume seed on about 2.5 million hectares annually.
All of the estimated 2.7 million tonnes of N fixed annually by legumes, growing on some 25 million hectares of land (including newly sown crop and pasture legumes and perennial and regenerating pasture legumes), can mostly be attributed to either current or past inoculation.

From the turn of the 20th century until around 1950, work on rhizobia, including manufacture of inoculants, was the domain of the state departments of agriculture. After 1950, however, the area sown to legumes – particularly subterranean clover and annual medics – increased dramatically and the demand for inoculants increased. Manufacture of inoculants was passed over to the private sector, and nodulation failures followed, which led to the creation of an independent quality control service, U-DALS, at the University of Sydney. Manufacture of inoculants remains with the private sector, now supported by an independent quality control laboratory, Australian Inoculants Research Group (AIRG).

**Inoculant groups**

The relationships between rhizobia and particular legumes are very specific so individual inoculants are produced for the different legumes used in Australian agriculture.

An inoculant or inoculation group covers a cluster of legumes nodulated by the same species of rhizobia (Table 1).

1 Both inoculant groups G and S can be used for lupin and serradella
2 Although group E is recommended for pea/vetch and group F for faba bean/lentil, if required group E can also be used for faba bean and group F used for pea/vetch

The rhizobia in each of the inoculation groups can be quite different. For example, lupins are nodulated by the slower-growing, acid-tolerant *Bradyrhizobium* species, while medics are inoculated by the fast-growing, acid-sensitive *Sinorhizobium* species.

The inoculant groupings provide a framework for:

- considering if inoculation is needed, based on the type of legume previously grown in a paddock; and
- choosing the correct inoculant for the particular legume to be sown.

Inoculants are produced and marketed commercially according to these inoculant groups. Choosing the correct inoculant group for a particular legume host (indicated by the letters AL for lucerne, N for chickpea, for example) is critical for effective nodulation and N fixation to occur.

**Benefits of inoculation**

After more than 100 years of legume cultivation, many Australian soils have developed substantial populations of rhizobia that are able to nodulate commonly grown agricultural legumes.

However, suitable rhizobia may still be absent from the soil if the legume has not been grown previously or where the soil is not conducive to long-term rhizobial survival. Here the benefits of inoculation can be dramatic.

Soil acidity, for example, can reduce the chances of rhizobia persisting. Rhizobia for medic, lucerne and pea (including faba bean, lentil and vetch) are particularly sensitive to acid soils.

In soils that have built up adequate populations of rhizobia, the communities can be diverse and may become less effective at fixing N over time when compared to commercial inoculant strains.

N fixation in nodules formed by soil rhizobia is sometimes less than 50 per cent of the level that is achieved in nodules formed by commercial inoculants.
The presence of less effective, established rhizobia populations in soil is not an impediment to the use of more effective inoculant strains. When applied in sufficiently high numbers inoculant strains can successfully compete with established soil rhizobia and replace them.

An example of the effect of adding inoculant rhizobia can be seen in Figure 1, which shows the results of trials of faba bean sown into soils that contained either nil-to-low populations of rhizobia or high populations. In the nil-to-low rhizobia soils, inoculation increased nodulation by more than 400 per cent and grain yield by 140 per cent. There were no nodulation or grain yield benefits of inoculation in the high-rhizobia soils.

**N fixation**

There are other, less obvious benefits of inoculation than improved nodulation and grain yield and higher crop biomass. Inoculation can also increase the amount of N fixed by the legume and the post-harvest (post-fallow) levels of soil nitrate.

In an experiment in southern NSW, inoculation increased grain yield of faba bean by 54 per cent and the amount of crop N fixed by a massive 700 per cent. See Table 2.

The benefit extended to post-fallow soil nitrate with levels increasing by 24 per cent, or 50kg N/ha.

With lupin, although the grain yield benefit of inoculation was marginal (six per cent) and the benefit for post-fallow soil nitrate was also marginal (10 per cent), the benefit for N fixation was large (360 per cent) (see Table 2).

**When do I inoculate?**

The challenge facing farmers is knowing when to inoculate. In the southern and western grain regions, only half of pea, vetch and lupin crops are inoculated, or about 500,000 out of one million hectares.

On the other hand, almost all of the 500,000 hectares of chickpea, mungbean and soybean in the northern grains belt are inoculated. Farmers are clearly making decisions about inoculation based on their experiences.

The book *Inoculating Legumes – a Practical Guide* and the *Backpocket Guide to Inoculating Legumes* include guidelines for whether or not to inoculate, (see Useful Resources). The book and guide contain recommendations for the 15 major legume inoculant groups. For guidelines for inoculant groups E (pea, vetch) and F (faba bean, lentil), see Table 3.

Legume inoculation represents a minor production cost with a potentially substantial payoff in terms of extra grain or biomass yield and extra N in the soil.

Inoculant quality

Inoculants manufactured and sold in Australia contain strains of rhizobia that have undergone thorough testing under laboratory, glasshouse and field conditions to ensure their local suitability.

Selection criteria include:

- strains that are highly effective in nodulation and N fixation across related legume species and cultivars of a particular species;
- strains that survive well on seed and in the soil after being introduced;
- strains that are genetically stable; and
- strains that are suitable for the manufacturing process.

In July 2010, the National Code of Practice and Quality Trademark for Legume Microbial Inoculant Products used in Australian Crops and Pastures, see Useful Resources, was introduced as part of a program to continually improve the quality and efficacy of biological inoculants marketed to Australian farmers.

Inoculant formulations (products)

There are several different commercial inoculant formulations available to farmers to allow flexibility of application.

- Peat inoculants – the oldest and most common form of inoculant used in Australia. These are prepared by mixing a broth culture of rhizobia into sterilised (gamma-irradiated) finely milled peat.
- Granular pellets or chips are made from either peat or clay and are impregnated with rhizobia.
- Freeze-dried powder, where a rhizobial broth culture is concentrated as a powder in a glass vial after all the water has been removed. The powder is reconstituted later on-farm.
- Liquid inoculants – suspensions of rhizobia in a protective liquid formulation.

Peat, freeze-dried and liquid inoculants can be applied either to seed or directly to soil in the seeding furrow. Granular inoculants are applied in-furrow.

If peat, freeze-dried or liquid inoculants are applied directly to soil, they are first suspended in clean potable water so they can be evenly distributed in the furrow.

At the time of publication, companies that are signatories to the National Code of Practice for legume inoculants and that are producing and selling inoculants carrying the Green Tick Logo are:

- BASF Agricultural Specialties Pty Ltd;
- New Edge Microbials Pty Ltd;
- Novozymes Biologicals Australia Pty Ltd; and
- Green Microbes Australia Pty Ltd

The Green Tick Logo indicates the packet or container of inoculant meets quality standards set and monitored by the Australian Inoculants Research Group (AIRG).

The Corporation and contributors to this Fact Sheet may identify products by proprietary or trade names to help readers identify particular types of products.

We do not endorse or recommend the products of any manufacturer referred to. Other products may perform as well or better than those specifically referred to. The GRDC will not be liable for any loss, damage, cost or expense incurred or arising by reason of any person using or relying on the information in this publication.

CAUTION: RESEARCH ON UNREGISTERED AGRICULTURAL CHEMICAL USE

Any research with unregistered agricultural chemicals or of unregistered products reported in this document does not constitute a recommendation for that particular use by the authors or the authors’ organisations.

All agricultural chemical applications must accord with the currently registered label for that particular agricultural chemical, crop, pest and region.
